Signal processing for digital optical disc players.

The dc coupled signal processor of the invention provides a method for accurately converting an analog input signal from a digital optical disc which signal has a finite rise time to a digital signal with accurately positioned edges by preserving the dc content of the input signal. A peak-to-peak detector detects the average of the peak-to-peak analog signals and feeds it to a low pass filter which operate above the periodic drift-like analog input signal. The output of this filter is employed as a reference voltage by a comparator which is used as a slicer or zero crossing detector. The comparator output is a digital signal with minimum bias distortion. The output of the filter is also fed to a differential amplifier and a second low pass filter which operates at a frequency below the cutoff of the periodic drift analog input signal.

The resulting signal is negatively fed back to the input to be summed and amplified with the input analog signal.

FIG.7

"Signal processing for digital optical disc players".

This invention relates to signal processors. More particularly, this invention relates to a signal processor having means for converting an analog signal into a digital signal with minimum bias distortion.

BACKGROUND OF THE INVENTION

A simple optical disc recorder/player may employ a first laser light to write data on an optical disc by burning holes or pits in the medium of the spinning disc. A second laser light recorder/player is usually employed to read the recorded data by reflecting light from the disc in places where a hole or pit has been burned away during recording. The reflected light passing through a set of optics is then applied to a photodetector array where the signals are detected and processed for subsequent utilization.

The playback signals from the optical disc is derived from a laser which has a finite beam size and is proportional to the convolution of the beam and the pits along the tracks of the optical disc. As the minimum pit size in the disc approaches the diameter of the laser beam, the pulse width of the recovered signal approaches the rise time, and the recovered signal approaches the shape of a sinusoidal wave. This signal is mixed with a very low frequency aperiodic thermal drift signal and with a periodic drift-like signal caused by changes in the reflectivity of the disc material.

Theoretically, by dc-coupling and linearly amplifying the signal from the photodiode preamplifier which are elements of the photodetector array, the location of the 50% point of the recovered signal is preserved but the signal is contaminated by noise for any channel modulation code with or without dc content. The use of ac coupling

causes the location of the transition of the 50% point to become distorted for a channel coded signal with dc content. The amount of distortion is directly proportional to the amount of dc content of the code.

5 The previously used method for converting an analog signal to a digital signal was to pass the analog signal through a low pass filter to establish an average dc level. This dc level was then applied to a comparator used as a zero crossing detector or slicer to provide a
10 digital output signal. This method leads to inaccuracies in the disc reading apparatus because the dc content of the input signal introduces an offset in the output signal from the low pass filter resulting in timing errors in the output of the slicer. These timing errors result from the fact
15 that the analog signal from the optical disc is mixed both with very low frequency aperiodic thermal drift and with a periodic drift-like signal caused by changes in the reflectivity of the optical disc material.

20 BRIEF DESCRIPTION OF THE INVENTION

To correct for the timing errors and thermal drift of prior art signal processors, the present invention provides means to detect the average peak-to-peak analog signal and to pass the average of this peak-to-peak signal
25 through a low pass filter with a cutoff above the periodic drift-like signal. The output of this filter is used as a reference voltage to a comparator which is used as a slicer and which provides a compensated digital signal output. At the same time, the average peak-to-peak signal is fed
30 to a differential amplifier and another low pass filter having a cutoff frequency below the frequency of the periodic drift-like signal. The resulting signal is negatively fed back to the input to be summed and amplified with the input analog signal.

35 BRIEF DESCRIPTION OF THE DRAWING

In the drawing:

Figs. 1A, 1B, and 1C show the relationship between the pit size in the optical disc and the recovered

signal under ideal conditions where the pit size is greater than the laser beam diameter;

Fig. 2 shows the waveforms of an ideal signal detector in which the rise and fall times of the output
5 signal have steep slopes;

Fig. 3 shows waveforms of a Miller code signal as effected by the high pass filter;

Fig. 4A shows waveforms of ac coupling versus dc coupling, Fig. 4B is an expanded view of the area A of
10 Fig. 4A;

Fig. 5 shows a schematic of the static threshold detector;

Fig. 6 shows the recovered signal amplitude fluctuation caused by variation in the disc reflectivity;
15

Fig. 7 is a block diagram of the dc coupled signal processor of the invention;

Fig. 8 shows the waveforms, the input analog signals, the compensated analog signal and the output digital signal of the dc coupled signal processor;
20

Fig. 9 is a block diagram of a signal processor similar to Fig. 8 with the addition of a gap detector, a timing circuit and a selection circuit for playing back a pregrooved optical disc; and

Fig. 10 shows the waveforms generated by the timing circuit and the sector gap of the signal processor of Fig. 9.
25

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring to Figs. 1A, 1B and 1C, the size of the pit burned into the optical disc during recording is
30 shown in Fig. 1A. As shown in Fig. 1A, the digital information is encoded at the halfway transition point of the recorded signal. Fig. 1B shows the diameter of the laser beam. Fig. 1C shows that as the laser beam approaches the minimum pit size the pulse width of the recovered signal
35 approaches the rise time causing the recovered signal to approach the shape of a sinusoidal wave. This is undesirable because the output signal from the signal processor becomes distorted.

Fig. 2 shows an ideal signal detector circuit which generates a TTL compatible digital signal from recovered signals. Of course, the ideal detector cannot be achieved and it is the purpose of the present invention to approach a signal output which closely resembles the ideal signal detector.

An analysis of the amount of bias distortion in a signal processor for a Miller modulated signal is discussed below with the description of a static dc coupled threshold detector and a dynamic dc coupled threshold detector. Bias distortion in the environment of a signal processor may be defined as the amount of lengthening or shortening of the output digital pulse caused by deviations of the threshold level away from the half amplitude level of the analog input signal.

In Fig. 3, waveform A shows a signal at the Miller Modulator output with maximum dc content. Waveform B is the dc coupled normalized playback signal after amplification and equalization. The dc content of the signal is shown by dashed lines at $\pm 1/3$ amplitude of the signal. The content of an ac signal is defined as the average voltage of the signal. The effect of the high pass filter on waveform B is shown in waveform C where τ_1 is the time constant of the high pass filter, having low frequency cutoff of $f_n = (2\pi\tau_1)^{-1}$. For the purpose of analysis and for deriving a formula for calculating edge distortion of the Miller signal, one cycle of the signal is shown for ac and dc coupling in Fig. 4(a). An expanded view of the area A is shown in Fig. 4(b). By analyzing the right-angle triangle formed by line ac with the y and t coordinates, Δt , the amount of distortion at the transition can be calculated.

The slope M_1 of line DC can be approximated by

$$M_1 \approx \frac{2A}{t_r}$$

where A is the peak amplitude of the dc coupled playback signal, and t_r is its rise time. The slope (M_2) of the line AC can be calculated

$$M_2 = M_1 + M_3,$$

where M_3 is the slope of dc content at the output of the high pass filter,

$$M_3 = \frac{d}{dt} \left[\frac{2}{3} (-e^{-t/\tau_1}) \right]_{t=0} = \frac{2}{3} \tau_1$$

Since M_1 is typically much larger than M_3 , (e.g. for a 4 rps optical recorder, $M_1 \simeq 100 M_3$), and $M_2 \simeq M_1$. The peak transition distortion, Δt can then be calculated

$$\begin{aligned} \Delta t &= \frac{\Delta y}{M_2} \approx \frac{\Delta y}{M_1} \\ &= \frac{\Delta y_{tr}}{2A} \approx \frac{t_r}{2A} \left[\frac{2}{3} A (1 - e^{-1/RC}) \right] \end{aligned}$$

For the Miller Signal, the pulse duration can be 1T, 1.5 T or 2T, therefore

$$\Delta t = \frac{t_r}{3} (1 - e^{-aT/\tau_1})$$

where $a = 1, 1.5$ or 2 .

As an example, for a 4 rps optical recorder (a data rate of 1.94 Mbit/s) using a high pass filter of 15 kHz, with a channel bandwidth (f_c) of 1 MHz, then, $T = 515$ nsec. yielding $\Delta t = 10.8$ nsec. For Miller code, the maximum transition error margin is $T/4$, i.e. 129 nsec, hence the 15 kHz high pass filter removes 8.4 % of this margin.

A static dc coupled threshold detector consists of a voltage comparator and a threshold control as shown in Fig. 5. The threshold voltage V_{th} is adjusted to the midpoint of the single ended signal V_1 for the detector to perform properly. Using dc amplification from the photodiodes to V_1 , the amount of thermal drift (Δv_d) of a differential pair of bipolar transistors can be calculated

$$\Delta v_d \approx A \left(\frac{2.2 \text{ mV}}{700} \right) \text{ per degree centigrade}$$

temperature change of the photodiode, where A = voltage amplification from photodiodes to V_1 . As an example, let the useful signal from the photodiodes be 1 mVp-p, with $A = 700$, then $V_1 = 700$ mVp-p, and $\Delta v_d \approx 2.2 \text{ mV}/^\circ\text{C}$.

For a 20°C temperature change (ΔT), the expected drift of V_1 is 44 mV. Since the disc channel bandwidth is limited and the signal has a finite rise time of t_r , the amount of timing error (Δt) is

$$\Delta t = \frac{V_t}{V_1} (t_r) \text{ where } \Delta V_t = \text{change in threshold}$$

voltage level = $\Delta v_d \times \Delta T$.

For a 4 rps optical recorder, $t_r \simeq 0.35 \text{ usec}$.

Then for $\Delta T = 20^{\circ}\text{C}$, the timing error due to thermal drift is

$$\Delta t = \frac{2.2 \times 10^{-3} \times 20}{700 \times 10^{-3}} \times 0.35 \times 10^{-6} \text{ sec.} = 22 \text{ nsec.}$$

The static detector requires a readjustment of the threshold level to account for different signal amplitudes due to disc to disc and player to player variation.

Further, even for the same disc, the reflectivity varies from one angular position to another, causing amplitude variation at the disc rotational rate. As shown in Fig. 6, timing error occurs everywhere except where the threshold is proper (A,B,C,D).

The maximum timing error is

$$\Delta t = \frac{\Delta V_1}{2V_1} (t_r)$$

where ΔV_1 = peak signal variation of V_1 as shown in Fig. 6.

In summary, static dc coupled threshold detection is not useful because the timing errors are not within permissible limits.

The dynamic signal dc coupled threshold detector of the invention shown in Fig. 7 automatically compensates for the thermal drift of the photodiode preamplifier and signal processor by means of a feedback loop in which the threshold voltage follows the envelope of the playback signal, thereby minimizing timing errors within permissible limits for the detector signal. In a dynamic dc coupled threshold detector there is no need for threshold voltage adjustment for different discs and players.

Input signal is applied to Summing Amplifier 10 is the analog optical disc playback signal from a dc coupled

preamplifier (not shown). Also applied to Summing Amplifier 10 is input b which is a feedback signal that compensates for any thermal drift of the photodiode preamplifier and the signal processor due to temperature or aging. The summed signals a and b from Summing Amplifier 10 are fed to Linear Phase Amplitude Equalizer 11. The signal output from Linear Phase Amplitude Equalizer compensates for high frequency response loss in the preceding stages. This signal is applied to Low Pass Filter 12 in order to filter out high frequency noise. The signal is fed to Amplifier Driver 13 where it is amplified and provides an output signal c. Signal c is fed to the positive terminal of Comparator 14 and to Peak-to-Peak Detector 15. Peak-to-Peak Detector 15 tracks the positive and negative peaks of signal c and provides two signal outputs f and g. Signal f is the positive peak signal and signal g is the negative peak signal. The signals f and g are fed to Adder Divider 16 where they are added together and then divided by a factor of 2. The output signal h of Adder Divider 16 is the average of signals f and g and it is applied to Low Pass Filter 17 to be filtered. The output signal d from Low Pass Filter 17 is fed to the negative terminal of Comparator 14. Signal d is the tracking threshold signal for accurate signal detection. Comparator 14 compares signal c at its positive terminal with signal d at its negative terminal and generates a thermally compensated digital signal processor output signal e with minimum bias distortion. Signal d from Low Pass Filter 17 is also fed to the positive terminal of feedback Difference Amplifier 18. A reference voltage V_r , is applied to the negative terminal of Difference Amplifier 18 generating a difference signal which is then fed to Low Pass Filter 19 and then to Summing Amplifier 10 to complete the feedback channel. Low Pass Filter 19 operates at a lower frequency than Low Pass Filter 17. The slowly varying signal b is subtracted from signal a in Summing Amplifier 10.

The dc coupled signal processor of Fig. 7 operates to detect the average of the peak-to-peak analog signal c

from Amplifier Driver 13 by means of Peak-to-Peak detector 15 and to pass this average peak-to-peak signal to Low Pass Filter 17 which operates at a cutoff above the periodic drift-like signal. The output of Low Pass Filter 17 is used
5 as a reference voltage for Comparator 14 which is used as a slicer. At the same time, the output of Low Pass Filter 17 is fed to Differential Amplifier 18 with a Low Pass Filter 17 having a cutoff below the frequency of the periodic drift-like signal. This provides signal b which is
10 negatively fed back to Summing Amplifier 10 to compensate for thermal drift. The waveforms of signals a, c, d and e are shown in Figure 11.

The choice of bandwidth of Low Pass Filter 17 needs some discussion. It should have a bandwidth larger
15 than the disc rotational speed so that amplitude modulation due to disc reflectivity variation can be followed by tracking threshold signal d. However, Low Pass Filter 17 should have a low enough bandwidth such that signal d is not sensitive to dropouts of signal c caused by disc
20 defects. Again, the bandwidth of Low Pass Filter 17 should be large so that the time delay of Low Pass Filter 17 is small for signal d to be a better threshold voltage when no dropout occurs. The optimal choice of bandwidth for Low Pass Filter 17 can only be determined by actual experiment.
25 From experiments, a bandwidth of 400 Hz is a good choice for a 4RPS recorder. The threshold voltage, d, is maintained very close to V_r , the reference voltage, by means of the feedback path consisting of the Difference Amplifier 18, Low Pass Filter 19 and Summing Amplifier 10. Thus, all the
30 thermal dc drift of the preamplifier and processor is automatically compensated.

Referring to Fig. 9, there is shown a signal processor essentially the same as Fig. 1 but for means added in order to playback a pregrooved disc. The blocks
35 which are similar to the blocks in Fig. 1 retain the same reference numeral and perform as already described. In the case of playing back a pregrooved disc, the Sector Gap Detector 30 has applied to its input signal a and it

generates a pulse indicating the beginning of the sector header. The output pulse from Sector Gap Detector 30 is fed to the Timing Circuit 31 which generates the correct timing pulse Y as shown in waveform B of Fig. 10. The timing pulse
5 from timing Circuit 31 switches Low Pass Filter 17 to a higher bandwidth such that the threshold signal d can respond quickly to the signal c amplitude change at the junction between the header and data field. Signal Y should end shortly after the beginning of the data field of waveform A.

10 The present invention provides the advantage in that it accurately converts the readback analog signal of an optical disc from the photodiode preamplifier into a digital signal for different modulation codes with or without dc content. Further, it compensates for thermal dc drift
15 of the photodiode preamplifier, other amplifiers, equalizer and filter. In addition, the playback signal from an optical disc is a band limited signal, having finite rise time and fall time. To convert this analog signal to a digital signal with sharp edges that carry the logical information, a
20 stripping level at the midpoint of the signal is used. Any signal above the stripping level is converted to a logic 1 and below the stripping level to a logic zero. In the circuit, the stripping level dynamically varies with the amplitude of the readback signal. In an optical disc, the
25 reflectivity varies across the surface of the disc generating signal amplitude modulation. Tracking the stripping level to the signal amplitude ensures accurate signal detection. Further advantages are that dropouts do not cause any problem because the stripping voltage time constant is long and at the moment a dropout is over, the
30 voltage is charged up quickly through a very short time constant path. In the pregrooved optical disc, the header data which includes data field gap period, but sync, word sync and track address is prerecorded. During playback, the
35 signal amplitude of the header and the data field is not the same as shown in Fig. 10. There is a step in the amplitude from the header to the data field. The circuit shown in

Fig. 9 can detect the playback signal from the pregrooved disc accurately.

From the foregoing, a signal processor for digital optical disc players having means to correct an analog signal from an optical disc with finite rise time to a digital signal with accurately positioned edges by preserving the dc content of the original analog signal has been shown. It is understood that changes and modifications may be made without departing from the scope of the invention which are incorporated in the claims hereinafter.

CLAIMS

1. A signal processor comprising:
a source of analog input signals,
means for generating a signal which compensates
for thermal drift of said analog input signals,
5 means for summing and amplifying said analog input
signals and said drift compensating signal to obtain an
error compensated signal,
means for detecting the peak-to-peak voltage of
said error compensated signal and for deriving a tracking
10 threshold signal, and
means for comparing said error compensated signal
with said tracking threshold signal for providing a digital
output signal with accurate positive and negative transit-
ions by preserving the dc content of said input signal.
15
2. The signal processor of Claim 1 comprising:
means responsive to said summing and amplifying
means for compensating for the high frequency response loss
of said error compensated signal, and
means responsive to said high frequency response
20 means for filtering out high frequency noise.
3. The signal processor of Claim 1 wherein said peak-
to-peak detecting means tracks the positive and negative
peaks of said analog input signal,
means for summing and dividing said positive and
25 negative peak signals to obtain an average of said peak-
to-peak analog input signals, and
means responsive to said summing and dividing
means for filtering said average peak-to-peak analog input
signals above the cutoff of said periodically drifting
30 analog input signal to provide a reference voltage to said
comparing means in order to determine the digital threshold
signal output.

4. The signal processor of Claim 3 comprising:
a reference voltage source,
means responsive to said reference voltage source
and said filtering means for providing a difference signal,
5 and a further means for filtering said difference signal
at a cutoff below the frequency of said periodic drift
analog input signal to provide said feedback signal for
compensating for thermal drift.
5. A dc coupled signal processor comprising:
10 a source of analog input signals,
a summing amplifier for amplifying said analog
input signal and a feedback signal to obtain an error com-
pensated signal,
a linear phase amplitude equalizer connected to
15 said summing amplifier for compensating for high frequency
response losses,
a first low pass filter connected to said linear
phase amplitude equalizer for filtering out high frequency
noise,
20 an amplifier and driver connected to said first
low pass filter for amplifying the output signal of said
first low pass filter,
a comparator having an output of said amplifier
driver connected to its positive terminal,
25 a peak-to-peak detector connected to the output
of said amplifier driver for tracking the positive and
negative peaks of said analog signal to provide an average
peak-to-peak signal as an output,
an adder and divider circuit connected to said
30 peak-to-peak detector for adding the positive and negative
peak signals and dividing said signals,
a second low pass filter connected to said adder
divider circuit having a cutoff frequency above the periodic
drift signal of said analog input signal for providing a
35 tracking signal to the negative terminal of said comparator,
said comparator comparing the signals at its positive and
negative terminals as slicer signals and providing at its

output a digital signal with accurate positive and negative transitions,

5 a difference amplifier having an output of said second low pass filter connected to its positive input terminal and a reference voltage connected to its negative input terminal to provide a difference signal of the average peak-to-peak signal, and

10 a third low pass filter connected to said difference amplifier having a cutoff frequency below the frequency of said analog input signal for providing a feedback signal compensated for drift to said summing amplifier.
